Motivation

Consider the following models.

Simple
1-parameter model: $y_n \approx w_0$

Complicated
2-parameter model: $y_n \approx w_0 + w_1 x_{n1}$

How can we *estimate* (or guess) values of \mathbf{w} given the data \mathcal{D} ?

$$e_n := y_n - f_{\mathbf{w}}(x_n)$$

↑ error

What is a cost function?

A *cost function* (or energy, loss, training objective) is used to learn parameters that explain the data well. The cost function quantifies how well our model does - or in other words how costly our mistakes are.

$$\mathcal{L}(\mathbf{w}) = \frac{1}{N} \sum_{n=1}^N \text{cost}(e_n)$$

Two desirable properties of cost functions

When the target y is real-valued, it is often desirable that the cost is *symmetric around 0*, since both positive and negative errors should be penalized equally.

Also, our cost function should penalize *“large” mistakes* and *“very-large” mistakes* similarly.

Statistical vs computational trade-off

If we want better statistical properties, then we have to give-up good computational properties.

Mean Square Error (MSE)

MSE is one of the most popular cost functions.

$$\text{MSE}(\mathbf{w}) := \frac{1}{N} \sum_{n=1}^N \underbrace{[y_n - f_{\mathbf{w}}(\mathbf{x}_n)]^2}_{e_n}$$

cost of point n

Does this cost function have both mentioned properties?

An exercise for MSE

Compute MSE for 1-param model:

$$f_w(x) = w_0$$

$$\mathcal{L}(w_0) := \frac{1}{N} \sum_{n=1}^N [y_n - w_0]^2$$

↖ $f_w(x_n)$

$w_0 =$	1	2	3	4	5	6	7
$y_1 = 1$	0 ²	1 ²	2 ²	3 ²	.	.	.
$y_2 = 2$	1 ²	0 ²	1 ²	2 ²	.	.	.
$y_3 = 3$	2 ²	1 ²	0 ²	1 ²	.	.	.
$y_4 = 4$	3 ²	2 ²	1 ²	0 ²	.	.	.
$\text{MSE}(\mathbf{w}) \cdot N$	14	6	6	14	30	54	
$y_5 = 20$	19 ²	18 ²	17 ²	16 ²	15 ²	14 ²	
$\text{MSE}(\mathbf{w}) \cdot N$	250	

Some help: $19^2 = 361, 18^2 = 324, 17^2 = 289, 16^2 = 256, 15^2 = 225, 14^2 = 196, 13^2 = 169$.

best model with 4

best model with 5

Outliers

Outliers are data examples that are far away from most of the other examples. Unfortunately, they occur more often in reality than you would want them to!

MSE is not a good cost function when outliers are present.

not very robust

Here is a real example on **speed of light measurements**

(Gelman's book on **Bayesian data analysis**)

28	26	33	24	34	-44	27	16	40	-2
29	22	24	21	25	30	23	29	31	19
24	20	36	32	36	28	25	21	28	29
37	25	28	26	30	32	36	26	30	22
36	23	27	27	28	27	31	27	26	33
26	32	32	24	39	28	24	25	32	25
29	27	28	29	16	23				

(a) Original speed of light data done by Simon Newcomb.

(b) Histogram showing outliers.

Handling outliers well is a desired *statistical* property.

Mean Absolute Error (MAE)

$$\text{MAE}(\mathbf{w}) := \frac{1}{N} \sum_{n=1}^N |y_n - f_{\mathbf{w}}(\mathbf{x}_n)|$$

Repeat the exercise with MAE.

w_0	1	2	3	4	5	6	7
$y_1 = 1$	0	1	2	3	4	5	6
$y_2 = 2$	1	0	1	2	3	4	5
$y_3 = 3$	2	1	0	1	2	3	4
$y_4 = 4$	3	2	1	0	1	2	3
$\text{MAE}(\mathbf{w}) \cdot N$	6	4	4	6	10	14	18
$y_5 = 20$	19	18	17	16	15	14	13
$\text{MAE}(\mathbf{w}) \cdot N$	25	22	21	22	25	28	

Can you draw MSE and MAE for the above example?

w_0^* , the optimal parameter

$w_0^* \in \{4, 3\}$

best model with 5
 $w_0^* = 3$

→ MAE is more robust to outliers
→ more hard to train (not differentiable)

= Computational advantage

Convexity

Roughly, a function is **convex** iff a line joining two points never intersects with the function anywhere else.

A function $h(\mathbf{u})$ with $\mathbf{u} \in \mathcal{X}$ is **convex**, if for any $\mathbf{u}, \mathbf{v} \in \mathcal{X}$ and for any $0 \leq \lambda \leq 1$, we have:

$$h(\lambda \mathbf{u} + (1 - \lambda) \mathbf{v}) \leq \lambda h(\mathbf{u}) + (1 - \lambda) h(\mathbf{v})$$

A function is **strictly convex** if the inequality is strict.

Importance of convexity

A strictly convex function has a unique global minimum \mathbf{w}^* . For convex functions, every local minimum is a global minimum.

Sums of convex functions are also convex. Therefore, MSE is convex.

as a function of weights \mathbf{w}

Convexity is a desired **computational** property.

Can you prove that the MAE is convex? (as a function of the parameters $\mathbf{w} \in \mathbb{R}^D$, for linear regression $f_{\mathbf{w}}(\mathbf{x}) := f(\mathbf{x}, \mathbf{w}) := \mathbf{x}^\top \mathbf{w}$)

$$\text{Cost} \left(y_n - f_{\mathbf{w}}(\mathbf{x}_n) \right)$$

ℓ_1

Computational VS statistical trade-off

So which loss function is the best?

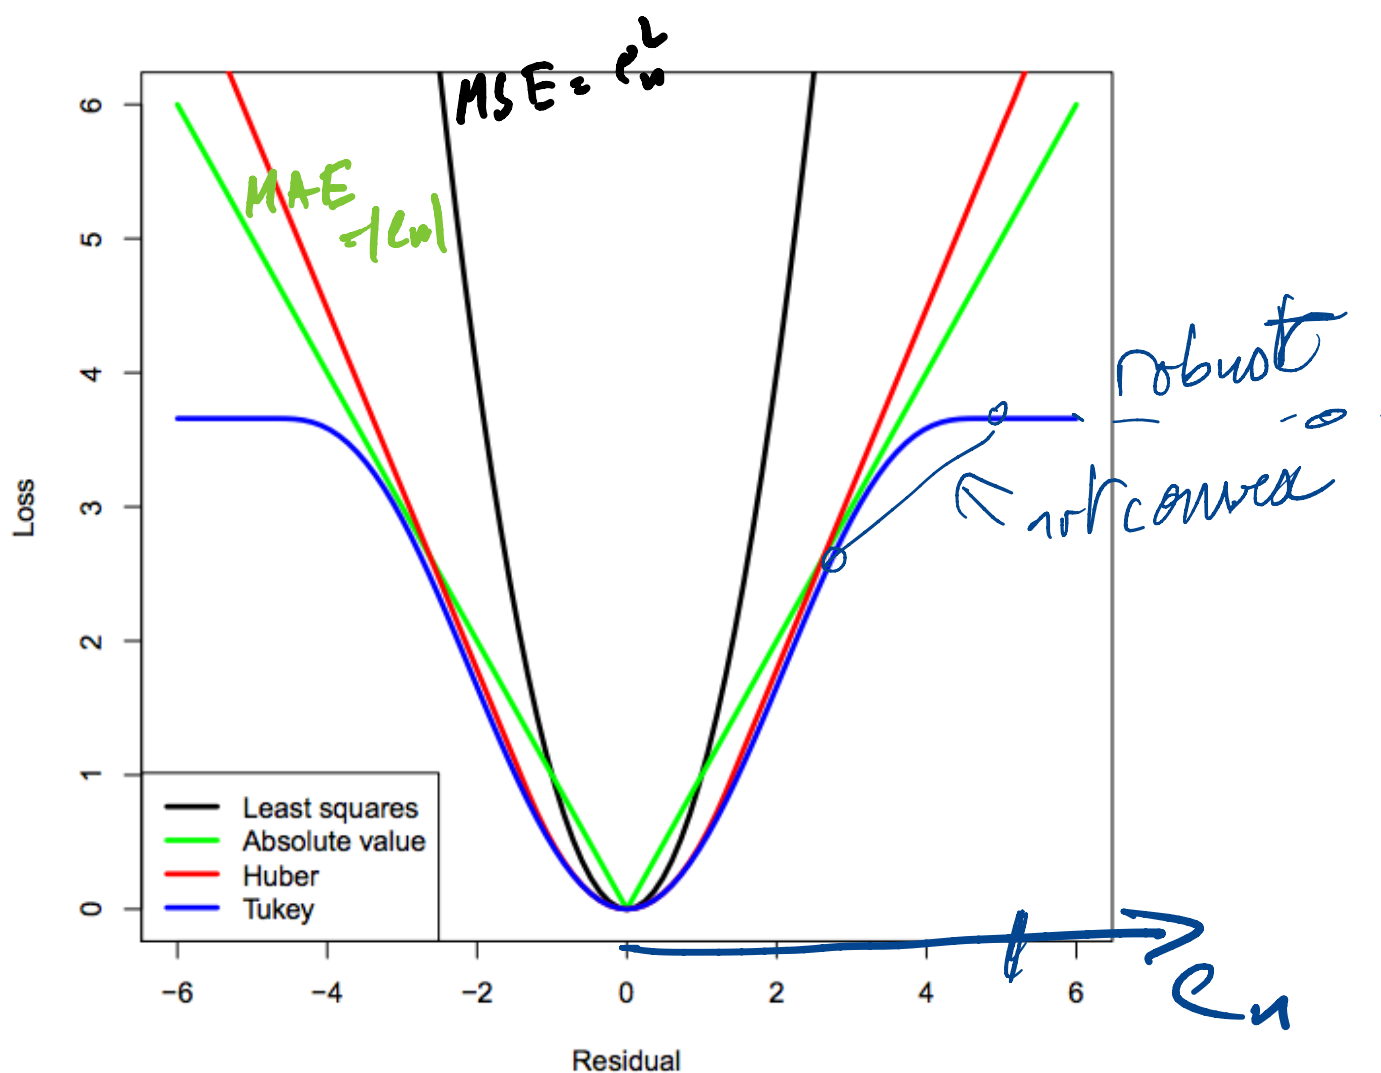

Figure taken from Patrick Breheny's slides.

If we want better statistical properties, then we have to give-up good computational properties.

Additional Reading (*not exam material*)

Other cost functions

Huber loss

$$Huber(e) := \begin{cases} \frac{1}{2}e^2 & , \text{ if } |e| \leq \delta \\ \delta|e| - \frac{1}{2}\delta^2 & , \text{ if } |e| > \delta \end{cases} \quad (1)$$

Huber loss is convex, differentiable, and also robust to outliers. However, setting δ is not an easy task.

Tukey's bisquare loss (defined in terms of the gradient)

$$\frac{\partial \mathcal{L}}{\partial e} := \begin{cases} e\{1 - e^2/\delta^2\}^2 & , \text{ if } |e| \leq \delta \\ 0 & , \text{ if } |e| > \delta \end{cases} \quad (2)$$

Tukey's loss is non-convex, but robust to outliers.

Additional reading on outliers

- Wikipedia page on “Robust statistics”.
- Repeat the exercise with MAE.
- Sec 2.4 of Kevin Murphy's book for an example of robust modeling

Nasty cost functions: Visualization

See Andrej Karpathy's Tumblr post for many cost functions gone “wrong” for neural networks. <http://lossfunctions.tumblr.com/>.
